Stability Analysis of Finger Millet Genotypes in Moisture Stressed Areas of Northern Ethiopia

Birhanu Meles  Mizan Tesfay  Chekole Nigus  Kiros Meles
Tigray Agricultural Research Institute, Axum Agricultural research Centre, P.O. Box 230, Axum, Ethiopia

Abstract
Finger millet is one of the important cereals in Ethiopia, preferred for food and local drink preparation and animal feed. In spite of its importance, yield is low due to production problems, such as lodging, moisture stress, disease (blast), weed, shortage of improved varieties and poor agronomic managements. Breeding of improved varieties with the farmers’ desired traits is one of the strategies of the national finger millet improvement programs. Multi-location trial is a basic task of breeding programs, for identifying and recommendation of a stable and high yielder variety. Nine advanced finger millet genotypes along with local check and standard check (Tadesse) were evaluated at moisture stressed finger millet growing areas of northern Ethiopia. Experiments were conducted in Rama during 2012, 2013 and 2014, in Ahferom during 2013 and 2014 and in Maistebri during 2014 cropping season, to select and recommend better performing stable genotypes. AMMI, ASV and GGE methods of genotype by environment interaction analysis, identified KNE#622 as relatively with low interaction accompanied with high grain yield performance, which can be recommended for moisture stressed areas. All the parameters indicated the local check and standard check were the worst varieties for their high interaction and low grain yield.

Keywords: Advanced lines, AMMI stability value Ethiopia, finger millet, genotype by environment interaction

1. Introduction
Selection of genotypes for wide adaptability is often limited by the existence of genotype by environment interaction, making the variety development process more complex and expensive. Multi-environment trials are among the basic procedure to identify and recommend superior cultivar with wide adaptation (Yan et al. 2001). Ethiopia as a general and the semi-arid environment in Tigray region, northern Ethiopia specifically has a wide environmental variability leading to high genotype by environment interaction (Conway 2000; Di Falco et al. 2007; Gebrehiwot et al. 2011; Meze-Hausken 2000). This strengthens the importance of multi-environment experiments in variety development process for successful variety recommendation in the area.

Different methods haven been used to explore genotype by environment interaction and identify superior genotypes with wide or specific adaptation for different environments. Currently most breeders are using the Additive main effects and multiplicative interaction (AMMI) analysis (Gauch 1992; Guach and Zobel 1997; Zobel et al. 1988) and the genotypes and genotype by environment (GGE) biplot analysis (Yan & Kang 2003; Yan & Tinker 2005; Yan et al. 2007). The advantages and disadvantages of the AMMI and GGE biplot analysis dealt with in detail by Gauch (2006) and Yan et al. (2007). The main difference between the two analyses is being that AMMI biplots the genotypes main effect is included as a multiplicative effect and not as an additive main effect (Yan and Kang 2003).

Finger millet (Eleusine coracana) is one of the orphan crops indigenous to east Africa (Vavilov 1951). In Ethiopia, the crop is among the food security crops, widely used for food, local beverage preparation and animal feed (Mulualem & Melak 2013). It is also nutritionally rich containing high ash, calcium and iron content, which is essential for strengthening bone and teeth and reduce incidence of anemia (Singh & Raghuvanshi 2012; Shobana et al. 2013). Finger millet has wide agro-ecology adaptation (Mbithi-Mwikya et al. 2000). Worldwide the crop has an area coverage of 33,810,000 ha with 29,900,000 ton production (FAO 2012). In Ethiopia finger millet ranks 6th of the cereals in terms of area coverage of 455417.19 ha and its productivity is 18.7 hat–1 (CSA 2014). While as compared to its genetic potential of 4-5 hat–1 (Dida et al. 2008), yield in Ethiopia is low, which is mainly due shortage of seed of improved variety, poor agronomic managements, high lodging, moisture stress, disease mainly blast and weeds (Fentie, 2012; Mulualem & Melak, 2013).

Developing improved varieties with high yield and wide adaptation is one of the major objectives of the national breeding finger-millet improvement program in Ethiopia. Yet, nationally about 13 improved varieties have released and varieties namely Tadese and Padet are among the relatively widely adopted varieties. Tadesse has been introduced in the finger millet growing areas of Tigray region. But its adaptation is limited because of its late maturity while a rainy season is becoming short in the areas. Similarly Gebre (2015) reported only 15% of the farmers adopted improved varieties in South zone of Omo, Ethiopia and the author added that, farmers prefer to grow the local varieties’ for their better grain yield, straw quality, grain color, early maturity, quality for local consumptions, weed tolerance, easy of threshing, and preference in market. Axum agricultural research center collaborate with the Ethiopian national finger millet improvement program based at Melkassa Agricultural Research Center, to conduct variety trials with the objective of identifying moisture stress tolerant varieties’
adaptable to the northern Ethiopia. Therefore the objective of this study was to select and recommend better yielder varieties with stable performance across moisture stressed areas of northern Ethiopia.

2. Materials and methods

2.1 Study Areas Description
Experiments were conducted in six environments; in Rama during 2012, 2013 and 2014; in Ahferom during 2013 and 2014 and in Maistebri during 2014 main production seasons. The altitude of Rama, Ahferom, and Maistebri were 1395, 2014, 1444 meter above sea level (m.a.s.l) respectively. The rainfall amount of the study areas was variable across seasons (Table 1) and the mean rain fall of ten years data indicates 717.1, 618.1 and 789.3 mm per annum for Ahferom, Rama and Maistebri, respectively. Even though the rainfall was intermediate concentrated during July and August, while low in the grain filling stages (September – October). Soil types were sandy in Rama and sandy loam in Ahferom and Maistebri, which were with low water holding capacity.

2.2 Planting Material and Experimental Management
Nine advanced finger millet genotypes developed for moisture stressed areas; namely Acc#29FMB/01WK/, KNE#622, KNE#741, KNE#1034, KNE#628, KNE#814, KNE#1012, Gulule, KNE#1149 and local check and standard check (Tadesse) were used in the study. Genotypes were laid down in RCBD design with three replications. Seed rate of ten kgha⁻¹ was drilled in 3 rows of 0.4 m inter-row spacing with 5 m length. Fertilizers in the form of Di-Ammonium Phosphate (DAP) and Urea were applied at 100 kg ha⁻¹ corresponding to environment data:

Where Υij is mean of genotype i in environment j, µi is described as the result of common fixed intercept term µ, a fixed genotypic main effect corresponding to genotype i, Gi, plus a fixed environmental main effect corresponding to environment j, Ej, while the GEI is explained by K multiplicative terms(k=1..K), each multiplicative term formed by the product of the singular values of the kth axis in the principal component analysis, a genotypic sensitivity bijk (genotypic score) and an environmental characterization zk (environmental score). And finally the random term eij, representing the error term, typically assumed normally distributed with a mean zero and variance; eij ~ N(0, σ2).

However, the AMMI model does not make provision for a quantitative stability measure, and as such a measure is essential in order to quantify and rank genotypes in terms of yield stability, the AMMI Stability Value (ASV) (Purchase et al. 2000) was worked out as follows:

\[ \text{ASV} = \frac{1}{2} \left[ \frac{(\text{IPCA1 sum of squares})}{\text{IPCA1 sum of squares}} + \frac{(\text{IPCA2 score})^2}{(\text{IPCA2 score})^2} \right] \]

Where, IPCA1SS and IPCA2SS stand for the sum of squares of IPCA1 and IPCA2, respectively.

To evaluate the test environments, which is not possible with the AMMI, the Genotype plus Genotype-environment (GGE) biplot analysis was carried out using the method suggested by Yan (2001) for multi-environment data:

\[ Y_{ij} - \mu_j = \lambda_1 a_{i1} y_{j1} + \lambda_2 a_{i2} y_{j2} + e_{ij} \]

Where Yij is mean of genotype i in environment j; µj is mean value of environment j; k is the number of principal components retained in the model; λ_1 and λ_2 the singular value of PC1 and PC2, respectively; a1i and a2i are the PC1 and PC2 scores, respectively, for genotype i; γ1j and γ2j are the PC1 and PC2 scores, respectively for environment j; and εij is the residual of the model associated with the genotype i in the environment j.

3. Results and discussion

3.1 Genotype yield and yield components performance across environments
Genotype Acc#29FMB/01WK/ was ranked first for its high grain yield in three environments (Rama2012, Rama2014 and Maistebri2014) while third in Rama2013, fourth in Ahferom 2014 and 7th in Ahferom2013...
(Table 2). However, due to its short plant height, low biomass yield and susceptibility to disease (head blast) (Table 3), this genotype was not selected by farmers. Finger millet is one of the preferred feed source crops, for its palatable straw (Mululem & Melak, 2013). Therefore, besides grain yield, biomass yield is among the major criteria for selection of a superior variety. The local check was least ranked in terms of grain yield in Rama 2012, Rama2013 and Rama2014, while fist ranked in Ahferom2013, third in Ahferom2014 and was fifth rank for its intermediate grain yield in Maistebri2014. The standard check was ranked tenth in Rama2013, Rama2014 and Ahferom2014, third in Rama2012, and eight in Maistebri2014 (Table 2).

Regarding the overall environment mean grain yield performance, Acc#29FMB/01WK/ was first ranked followed by KNE#622, whereas local and standard check were least ranked for their low grain yield performance. Highest environmental mean grain yield was showed in Rama2013, followed by the grain yield in rama2014 and ahferom2014. Least mean grain yield was observed in ahferom2013 (Table 2).

3.2 AMMI ANOVA

AMMI ANOVA (Table 4) indicates significant (P≤0.01) effects of genotypes, environments and genotype by environment interaction, indicating the high environmental variations and differential response of genotypes to the variable environments thus leading to inconsistency ranking of genotypes. Lule et al. (2014) reported significant genotype by environmental interaction for finger miller varieties tested across four locations for two seasons in Ethiopia. Highest (37.4%) variation was explained by environment effect, followed by genotype by environment interaction and genotypes explaining 23.2% and 8.5% of variation, respectively. This may indicate the existence of a considerable amount of deferential response among the genotypes to changes in growing environments and the differential discriminating ability of the test environments. Adugna et al. (2011) reported 79.13, 18.34 and 2.53% of variation explained by environments, genotype by environment interaction and genotype respectively for finger millet genotypes tested over ten environments in Ethiopia. The genotype by environment interaction effect was almost three times higher than the genotypes effect. IPCA1 and IPCA2 were significant explaining 54.4 and 22.1% of the interaction, respectively, leading to a cumulative of 76.5% of variation and the rest 23.5% was contributed due to noise (Table 4).

3.3 AMMI Biplot: classification of genotypes and environments

The AMMI biplot based on the relative magnitude of the position and direction of genotypes on the plane of stability parameter regressed on the environmental mean yields is considered an important measure of the pattern of adaptation and stability (Zobel et al. 1988). Figure 1 presents plotting of the first IPCA against the mean for both the genotypes and environments. Genotypes KNE#1012 and KNE#741 was close to the origin (x-axis) and with above mean grain yield, indicating their low interaction to environmental changes accompanied with intermediate grain yield performance. According to Annicchiarico (1997) a stable genotypes should be that with low interaction to environmental changes and high yielder. Accordingly, Genotype KNE#622 was second high grain yielder and relatively low interaction, being as stable genotype. Genotype Acc#29FMB/01WK/ on the other hand showed highest mean grain yield however high IPCA1 indicating its relatively high interaction to environmental changes (Figure 1).

Majority of the genotypes and environments were plotted in the first and fourth quadrant of the biplot (Figure 1). Rama2013 and Ahferom2014, plotted on the first quadrant for their high mean grain yield while with high interaction and Maistebri2014 was also in this quadrant but relatively with low interaction. Genotypes Acc#29FMB/01WK/, KNE#622 KNE#814, and KNE#628 were in this quadrant for their similar performance and the same IPCA sign. Rama2014 was in the fourth quadrant for its above mean grain yield and negative IPCA1 and genotypes KNE#1012, KNE#741, gulule and KNE#1034 showed the same IPCA1 sign. Ahferom2013 was plotted in the third quadrant for its low mean grain yield and negative IPCA1 which was far from the origin and the local variety and standard check (Tadesse) were in this quadrant far from the origin, indicating their low grain yield performance and high interaction (Figure 1). Differential responses of genotypes in low and high yielding environments often reflect the consequences of differences in rainfall regimes (Soliman & Allard 1991; Vanooosterom et al. 1993; Voltas et al. 1999c). Similarly, rainfall variability across location and seasons within the location was observed in the current study environments (Table 1), which was the main cause for the inconsistent genotype performance.

3.4 Correlation of test environments

Yield from the three seasons in Rama was positively correlated. This guarantees that, selection of a variety for its performance in this location could be done based on one season result. Tolessa et al. (2013) reported the advantages of information on the correlation of testing environments in deciding on the number of testing environments and seasons to be used for testing a variety performance. Yield in Ahferom2013 was negatively corrected with all the environments and Ahferom2014 was negatively correlated with all environments except with Rama2014 and Maistebri2014. This indicates that Ahferom was low yielding environments and even within
the location, seasons were variable, which could be mainly, due to the erratic rain fall. Yield in Maistebri2014 was positively correlated with all environments except with yield from Ahferom2013 (Table 5).

3.5 AMMI stability value (ASV)
ASV was proposed to rank genotypes based on their stability and mean yield (Purchase et al., 2000). ASV is the distance from zero in a two dimensional scatter gram of IPCA1 scores against IPCA2 scores. Since the IPCA1 score contributes more to genotype by environment interaction sum of square, it has to be weighted by the proportional difference between IPCA1 and IPCA2 scores to compensate for the relative contribution of IPCA1 and IPCA2 to the total genotype by environment interaction variation. Stability per se should however not be the only parameter for selection, because the most stable genotypes would not necessarily give the best yield performance (Mohammadi & Amri 2008). Hence there is a need for approaches that incorporate both mean yield and stability in a single index, that is why various authors introduced different selection criteria for simultaneous selection of yield and stability (Eskridge 1990; Kang 1993; Dashiell et al. 1994; Bajpai & Prabhakaran 2000; Rao & Prabhakaran 2005; Farshadfar 2008; Babarmanzoor et al. 2009). Genotypes KNE#1012, Tadesse (standard check) and KNE#741 ranked first, second and third respectively, for their low ASV value, however these genotypes were with low mean grain yield (Table 6). AMMI biplot (Figure 1) also revealed low interaction of these genotypes for the environmental change. KNE#622, the second high yielding genotypes was ranked fourth for its intermediate ASV value, which can be considered as relatively stable. The high yielding genotype, Acc#29FMB/01WK/ and intermediate yielding genotypes KNE#628 and KNE#814 ranked ninth, eight and seventh in that order, for their high ASV. The local check was ranked eleventh for its high ASV value, indicating its high interaction (Table 6).

3.6 Genotype and genotype by environment interaction (GGE) biplot analysis
3.6.1 Relationships among the test environments
GGE biplot, which was based on environment focused scaling, was used to estimate the pattern of environments (Figure 2). Environment has showed negative and positive Principal component (PC) score indicating that there was a difference in rankings of yield performance among genotypes across environments leading to a cross-over genotype by environment interactions. To visualize the relationship between environments, lines are drawn to connect the test environments to the biplot origin known as environment vectors. The cosine of the angle between two environments is used to approximate the correlation between them as described and used in Dehghani et al. (2010), Kaya et al. (2006). Accordingly Rama2012, Rama2013, Rama2014 and Maistebri2014 were positively correlated. Rama2014 and Ahferom2014 were not correlated. The presence of wide obtuse angle (that is, strong negative correlations) among test environments is an indication of high cross over genotype by environment interaction (Yan and Tinker 2006). Rama2013, rama2014 were negatively correlated with ahferom2013 and ahferom2014. Rama2014 for its high yield and Ahferom 2013 for its low yield showed strong negative relationship (Figure 2).

The distance between two environments measures their dissimilarity in discriminating the genotype, therefore Rama2014, Rama2013 and Ahferom2014 were far from the origin indicating their higher discriminating ability for the genotypes, while Ahferom2013 and Maistebri2014 were the least discriminating environments (Figure 2).

3.6.2 Identification of best performing finger millet varieties
The polygon view of the GGE biplot is presented in Figure 3. This biplot indicates the best performing genotype(s) for each environment and the group of environments (Yan & Hunt 2002). The rays of the biplot divided the plot in to six sections. The environments appeared in three of them, revealing three mega environments. According to Yan et al. (2007), when different environments fell in to different sectors, it implied that they had different high yielding cultivars for those sectors and it showed cross over genotype by environment interaction, suggesting that the test environments could be divided in to mega-environments. The vertex families for each quadrant represented the genotypes with the highest yield for the environment that fell within it. The highest yielding genotype in Maistebri2014 was Acc#29FMB/01WK/. In Ahferom2014 genotypes KNE#1034 showed specific adaptation. The local check was low yielding with specific adaptation in Ahferom2013 (Figure 3). The standards check (Tadesse), KNE#741 and KNE#1149 were also low to intermediate yielding genotypes (Figure 3). Yan & Tinker (2005) described the ideal genotypes as having high yield and stable across environments.

3.6.3 Ranking of genotypes based on mean yield and stability
Figure 4 presents the mean grain yield and stability of genotypes. Yan et al. (2001) described high yielding and stable genotypes, should be close to the origin and had the shortest vectors from the Average environment coordinate (AEC) lines. Accordingly, genotype KNE#622 was the second large yielder genotype and shortest AEC, indicating its stable performance and genotype Acc#29FMB/01WK/ was the first high yielding while with intermediate AEC, indicating its relatively high interaction to environmental changes (Figure 4). Genotypes
KNE#628 and KNE#814 were also with above mean grain yield performance and relatively short length from the AEC. The local and standard check varieties were the worst in terms of grain yield performance and stability, for their high vector from the AEC and PC1 below 0.

4. Conclusion
The investigated stability analysis parameters (AMMI, ASV and GGE) enabled to classify genotypes and environments for their stability. AMMI, ASV and GGE identified KNE#622 as relatively with low interaction accompanied with high grain yield performance. All the parameters indicated the local check as worst variety for its high interaction and low grain yield. The GGE biplots gave more visual interpretations than just selecting the best performing genotypes and it also allowed visualization of cross over genotype by environment interaction through the polygon view. Over all, the AMMI and GGE biplot analysis resulted in more or less similar selections of superior, stable genotypes and classification of environments.

5. Acknowledgments
The Authors would like to acknowledge Melkassa Agricultural Research Center (MARC) for providing the planting materials and Axum Agricultural Research Centre (AxARC) is also acknowledged for providing the necessary material and technical support during study.
